ABSTRACT
Experimental measurements of heat load profiles from infrared thermography in L-mode plasmas from two tokamaks, JET and ASDEX Upgrade, are presented. The power decay length ($\lambda_q$) is extracted via a fitting procedure. The basic dependencies of $\lambda_q$ are identified through plasma parameters scans and for the case of fully attached divertor using numerical regressions (after mapping at the mid-plane). The results are compared with previously published H-mode data. Qualitatively, similar trends with the safety factor, toroidal magnetic field and heating power are found though bulk data is about a factor of two larger in L-mode for both devices. Consistently a clear shrinking of the heat channel width is observed at the L-H transition linked with the formation of the pedestal temperature. Extrapolation of the empirical power scaling laws to ITER gives $\lambda_q \approx 3.0-4.9$mm for L-mode plasma.

1. INTRODUCTION
Although power dissipation in the divertor will ultimately determine the target peak heat load ($q_{\text{max}}$), the power decay length in the SOL above the X-point region $\lambda_q$, is a crucial quantity governing exhaust dynamic in tokamaks. For instance, achievement of detachment is expected to depends strongly on $\lambda_q$. Also, during the discharge evolution (L-to-H, H-to-L, instabilities etc...), enough power dissipation may not be reached at all times resulting in a power deposition directly linked to $\lambda_q$. Despite the importance of an accurate prediction of $\lambda_q$, a commonly accepted theoretical model or empirical extrapolations from current devices to ITER remain elusive [1]. In recent work [2], outer target heat flux profiles from the JET and ASDEX Upgrade tokamak have been used to derive the inter-ELM $\lambda_q$ H-mode [2] with fully attached divertor. Low recycling attached divertor represents the best possible condition to infer $\lambda_q$ from target data when others, more direct measurements, are not available. In this case it is found that the target heat flux profile from thermography can be represented as the convolution of an exponential function with decay $\lambda_q$ and a gaussian of width $S$, as due to a residual radial diffusion in the divertor. The results were used to extract a scaling law for $\lambda_q$ (magnetically mapped at mid-plane dividing by the flux expansion $f_\chi$) with plasma parameters and successfully compared with an heuristic model [3]. These results have been confirmed by similar analysis in DIII-D and C-Mod [4]. To further test and complete the physical understanding the effect of ELMs, plasma density and confinement must also be clarified. In this work we apply the same methodology as in [2] to L-mode plasmas from the JET and ASDEX Upgrade tokamaks. Since it is desirable to achieve the L-H transition at relatively low plasma density, due to the lower power threshold, $\lambda_q$; L-mode may also have direct impact on the H-mode accessibility and operation of large devices such as ITER.

2. THE L-MODE DATABASE AND THE ANALYSIS
We consider only discharges with carbon divertor plasma-facing components. The present database includes, respectively, 19 hydrogen and 21 deuterium JET plasmas, and 29 deuterium AUG plasmas.
L-mode helium plasma are available for both machines and will be included in the database in the future. Important parameters are summarised in Table 1. We denote plasma current as $I_{p,\text{toroidal}}$, magnetic field as $B_T$, edge safety factor as $q_{95}$, heating power as $P_h$, triangularity as $\delta$, and the plasma density as $n_p$. The aspect ratio of both machines, defined as $\varepsilon = a/R_{\text{geo}}$, is $\varepsilon = 0.32$, with the major geometrical radius denoted as $R_{\text{geo}}$ and the minor radius as $a$. The plasma elongation amounts to $\kappa = 1.6$ for both devices. Different divertor plasma conditions are included, ranging from fully attached low recycling with peak target temperature of around 30eV to partially detached with target temperature of few eV. The JET database contains limited $q_{95}$ and $P_h$ scans in hydrogen and density scans in deuterium. The AUG database is relatively old (discharges performed between 2002-2006) and sparse with no dedicated experiments.

2.1 Characterisation of heat flux profile and the extraction of the decay length

The SOL power decay length is determined by analysis of heat flux profiles measured at the outer divertor target by means of infrared thermography. Details of the experimental setup for JET can be found in [5] and for AUG in [6].

Following [2] and expressing the target coordinate as $s$ and the strike line position on target as $s_0$ we describe the heat load profile at the divertor entrance as

$$q(s) = q_0 \cdot \exp\left(\frac{-s}{\lambda_q}\right) \quad \text{and} \quad \bar{s} = s - s_0 \quad s \geq s_0$$  \hspace{1cm} (1)

This simple ansatz allows to account for perpendicular heat diffusion or leakage into the Private-Flux-Region (PFR) by introducing a Gaussian width $S$ representing the competition between parallel and perpendicular heat transport in the divertor volume. This means that, physically, the exponential profile at the divertor entrance [7], is diffused into the private flux region while travelling towards the target [8]. This competition is approximated by a convolution of the exponential profile with a gaussian function with the width $S$. Neglecting the flux expansion $f_x$ the target heat flux profiles are thus expressed as ($s \in [-\infty, \infty]$)

$$q(s) = \frac{q_0}{2} \exp\left(\frac{-s}{2\lambda_{q1}}\right) \cdot \left(1 - \frac{s}{S}\right) + q_{BG}$$  \hspace{1cm} (2)

Figure 1 shows two examples, one for JET and one for AUG, of the measured heat flux profiles and fitting results by using Eq.2 with the free parameters $S, \lambda_{q1}, q_0, q_{BG}$ and $s_0$. In the figure we also depict the extrapolated exponential heat flux profile from Eq.1. Note that this procedure allows an independent estimation of the strike point position at the target. From Eq.2 follows the integral power decay width [9]

$$\lambda_{int} = \frac{\int q(s) - q_{BG})ds}{q_{max}}$$  \hspace{1cm} (3)
This quantity is frequently used in the literature [9] since it allows to relate the peak heat load on the divertor target to power deposited on the divertor target, a crucial design parameter for the power handling capabilities of a large device such as ITER. Within the framework model of Eq.2 the relation between exponential and integral decay lengths can be written with good approximation as (also neglecting \( q_{\text{BG}} \)) [4]

\[
\lambda_{\text{int, model}} = \lambda_q + 1.64S
\]  

As figure of merit for the fit quality we plot in figure 2, and for the entire database, the ratio \( \lambda_{\text{int}} / \lambda_{\text{int, model}} \) with \( \lambda_{\text{int}} \) calculated from the experimental profiles using Eq.3. It can be seen that this ratio is always close to one indicating satisfactory fit. Small systematic deviation (ex. for the AUG data) can be mainly ascribed to the residual background in the heat flux profile. It is quite surprising that this simple model equation fits well heat flux profiles also in presence of partial power detachment where complex physical processes are already taking place in the divertor volume. This complex physics can apparently be captured by the effective radial diffusion parameterised by the gaussian width \( S \).

More importantly, it should be noted that any physical study of the SOL power decay length should use \( \lambda_q \) and not \( \lambda_{\text{int}} \) which has a stronger dependence on the divertor physics as seen from Eq.2. For instance attempts to regress the data would lead to different results if using \( \lambda_q \) or \( \lambda_{\text{int}} \).

3 \( \lambda_q \) DEPENDENCE ON BASIC PLASMA PARAMETERS

Basic main plasma dependencies are best studied using systematic parameter scans (while fixing all others as much as possible) in a single or subsequent discharges. Within the present database we have available very limited \( q_{95} \) scan (at fixed \( I_p \)) at two different \( P_h \) in JET hydrogen plasmas and density steps in JET deuterium plasmas. Despite this limitation, figure 3 shows a clear monotonic increase of \( \lambda_q \) with \( q_{95} \) for both \( P_h \) values. Also, \( \lambda_q \) is larger for higher heating power at the same safety factor. Note that these scans are performed at fixed \( I_p \) thus \( q_{95} \propto B_t \). The observed behaviour can be equally attributed to the toroidal field. No \( q_{95} \) scan at fixed \( B_t \) are available. To disentangle these dependencies a parametric regression of the decay length is showed in the next section which confirms the role of the safety factor.

In the following we concentrate on fully attached (generally low density) plasmas leaving the discussion of \( n_p \) effect for future publication. We only anticipate that, for fixed input power, a moderate plasma density variation has a weak effect on \( \lambda_q \) while is more evident on the diffusion parameter \( S \) which tends to increase leading to a more ‘Gaussian shaped’ profile (with much smaller \( q_{\text{max}} \)).

4. SCALING OF \( \lambda_q \) IN AUG AND JET L-MODE PLASMAS

We apply least square fitting to derive a parametric dependency of the power decay length. To
make the data from both devices more homogeneous and to allow better extrapolation of the SOL properties of \( \lambda_q \): i) select plasmas with fully attached target condition having low upstream density (JET criterion) and peak target electron temperature above 8eV (AUG criterion). ii) We select fits with \( S/\lambda_q < 0.60 \). This is because two-dimensional numerical heat diffusion calculations [10] using Spitzer parallel and Bohm perpendicular thermal diffusivities show that using Eq.2 is accurate to better than 5% in determining \( \lambda_q \) at the divertor entrance in cases where the deduced Gaussian width \( S \) is less than 60% of the exponential width \( \lambda_q \). After data selection we have 15 hydrogen and 7 deuterium JET plasmas and 13 deuterium AUG plasmas. iii) In order to relate the surface heat flux profile to the outer midplane separatrix region, the magnetic flux expansion, \( f_x \), has to be taken into account. We use the definition for an integral flux expansion along the target surface [6,9] calculated for the outer midplane region \( R = R_{\text{sep}} \) to \( R = R_{\text{sep}} + 5\text{mm} \), with \( R_{\text{sep}} \) being the outer separatrix radius. Thus we define and regress the quantity \( \lambda_q \equiv \lambda_q / f_x \) using the following variables: toroidal field \( B_T \), cylindrical safety factor \( q_{\text{cyl}} \) (for JET only) or edge safety factor \( q_{95} \) (for AUG and combined data from both devices), power crossing the separatrix \( P_{\text{SOL}} \) and \( R_{\text{geo}} \) when regressing combined data. We assume the following functional dependency:

\[
\lambda(\text{mm}) = C_0 \cdot B_T^{C_B} (T) \cdot q^{C_q} \cdot P_{\text{SOL}}^{C_P} (\text{MW}) \cdot R^{C_R} (\text{m})
\]

(5)

The selected data showed no statistically significant dependence on the plasma density and it is thus excluded from the fit parameters (despite a non negligible variation \( n_p = 1.9 - 4.2 \times 10^{19} \text{ m}^{-3} \)). The summary table 2 shows the data used for each regression, the exponent and error bars for each variable and the quality of the fit (degrees of freedom adjusted correlation coefficient \( R^2 \)). The quality of the fit changes considerably from case to case and the error bar on parameters can be large. Nevertheless and quite remarkably, we find the same qualitative dependencies for all combinations of data used. Namely a nearly linear increase of \( \lambda_q \) with the safety factor which is always the parameter with the largest exponent. In general no satisfactory fit can be obtained without using this variable. A still positive but much weaker dependence on \( P_{\text{SOL}} \) and a negative \( B_t \) with an exponent ranging between \(-0.8 \div -0.4 \) for combined database. The highest correlations are found by using hydrogen JET data only and hydrogen JET plus AUG data (80% of the database). This latter case is also plotted in figure 4. In this case the scaling law reads as:

\[
\lambda_q = 1.44 \pm 0.67 \cdot B_T^{-0.8 \pm 0.32} \cdot q_{95}^{1.4 \pm 0.67} \cdot P_{\text{SOL}}^{0.22 \pm 0.10} \cdot R^{-0.03 \pm 0.28}
\]

(6)

Two important results must be pointed out. First, the L-mode scaling in Eq.6 (as well as the one of JET hydrogen only) is very similar to the JET H-mode scaling (see table 2 in [2]) with the exception of the double proportional coefficient, suggesting a tendency for larger \( \lambda_q \) in L-mode. Second, the major R dependence is basically negligible, again similar to the previous finding in H-mode. The regression of the entire database, including JET deuterium, is shown in figure 5. The most important
difference is the appearance of a major R dependency. We believe this is mainly an artifact. The inclusion of R in the regression in fact does not improve substantially the fit quality (see last row of table 2) and the associated uncertainty is larger than the exponent itself. This large uncertainty is due to the large cross-correlation with $P_{\text{SOL}}$ within this database (large $P_{L-H}$ threshold for larger machine). These results are different from the L-mode scaling law developed by A. Loarte et al. in [9], especially regarding the major R and $q_{95}$ dependency. Our L-mode scaling it is closer, in terms of main dependencies, to the H-mode scaling proposed also in [9]. One reason is that here we concentrated on the attached L-mode cases only where divertor effects are, in principle, minimised.

5. COMPARISON WITH H-MODE PLASMAS
The results of the previous section suggest the need of a more detailed comparison between L-mode and H-mode data. Figure 6 show a comparison of $\lambda_{q,L-mode}$ with the H-mode scaling law $\lambda_{q,H-mode} = 0.73 \cdot B_t^{-0.78} q_{1.20}^{1.20} P_{\text{SOL}}^{0.10} R^{0.02}$. We can see that for most cases $\lambda_{q,L-mode}$ is 2–3 times larger than predicted by the scaling law. This is expected since radial transport in L-mode is larger than in H-mode in the main plasma, SOL and apparently also in the divertor as suggested by larger diffusion parameter S (not shown). This feature becomes more evident when looking at the heat flux profiles during an L-H transition as illustrated in figure 7 for a JET deuterium plasma. The NBI power step-up initiates a fast temperature increase. After about 100ms a dithering phase visible in the integrated power to the target and H signal (not shown) coincides with a sudden shrinking of the heat flux channel with a reduction of $\lambda_q$ by almost a factor of 2. After other 200ms $\lambda_q$ has reached its ELM-free H-mode value which is in line with inter-ELM scaling (see figure 6). Also S decreases by about 30% in the ELM-free H-mode regime. Analysis of the kinetic profiles shows that the shrinking of the heat flux channel is linked with the changes in the pedestal temperature (pedestal density evolves much more slowly). The rapid change in $\lambda_q$ around $t = 63.65s$ happens in few tens of ms, much shorter time than the energy confinement time. Stationary heat flux profile is reached when $T_e$ pedestal has reached about 90% of its final value.

This observation may have important consequences for the operation of large device such as ITER reducing the H-mode accessibility. In fact, the ELM-free period before the first ELM (lasting in this case more than 0.5s) will be a very critical one in terms of heat loads. Not only the exhaust channel has become very narrow (perhaps even narrower than the H-mode scaling in [2] predicts), but during this period the broadening affect associated with the strike point movement during ELM cycle [2] is also absent as only a 5-6mm slow drift of the peak heat flux is observed.

SUMMARY AND DISCUSSION
We have constructed and analysed a database of heat flux profiles for JET and AUG L-mode plasmas. The fitting procedure successfully applied to H-mode plasmas works well also for L-mode, both with attached and partially power detached divertor. Despite certain quantitative variation, we find, for fully attached cases, positive trend of $\lambda_q$ with the safety factor ($\sim q_{95}^{0.73+1.14}$) and input power
\[ \left(\sim P_{\text{SOL}}^{0.13-0.29}\right) \text{ and negative dependence with the toroidal field } \left(\sim B_t^{-0.80-0.40}\right). \] Although a weak dependence on machine size cannot be completely excluded within the present database, it is however very unlikely. If confirmed, this similarity with the H-mode scaling call for theoretical understanding lacking at present. We find no clear difference between hydrogen and deuterium plasmas. The numerical coefficients of the empirical power scaling law found here in L-mode and the one in H-mode \cite{2} are in agreement within error bars except a proportionality factor about two times larger for L-mode. This same result is found when looking at \( \lambda_{\text{q}} \) during the L-H transition which shows a sudden reduction linked with the pedestal temperature change. The L-H transition will be a very critical phase for the exhaust control during ITER operation. We finally extrapolate these results to the \( \lambda_{\text{q}} \) in ITER L-mode (see last column of table 2) using the design value \( R = 6.2\text{m}, a = 2.0\text{m}, \kappa = 1.7, B_{\text{tor}} = 5.3\text{T}, I_p = 15\text{MA}, q_{95} = 3.0 \) and a maximum L-mode SOL power \( P_{\text{SOL}} = 50\text{MW} \) before transition to H-mode. We find \( \lambda_{\text{SOL}} \approx 3.0-4.9\text{mm} \), which, although smaller than currently predicted, should pose no serious problem to the machine operation.
