Abstract.

Quasi-Coherent (QC) modes have been reported for more than 10 years in reflectometry fluctuations spectra in the core region of fusion plasmas. They have characteristics in-between coherent and broadband fluctuations as they oscillate at a marked frequency but have a wide spectrum. This work presents further evidences of the link recently established between QC modes and the Trapped Electron Modes (TEM) instabilities [H. Arnichand et al., Nucl. Fusion 54 123017 (2014)]. In electron cyclotron resonance heated discharges of Tore Supra, an enhancement of QC modes amplitude is observed in a region where TEM cause impurity transport and turbulence. In JET Ohmic plasmas, QC modes disappear during density ramp-up and current ramp-down. This is reminiscent of Tore Supra and TEXTOR observations during transitions from the Linear Ohmic Confinement (LOC) to the Saturated Ohmic Confinement (SOC) regimes. Evidencing TEM activity becomes then experimentally possible via the analysis of fluctuation spectra.

Keywords: turbulence, micro-instabilities, trapped electron modes, electron cyclotron resonance heating, ohmic confinement, reflectometry
Discriminating the Trapped Electron Modes contribution in density fluctuation spectra

Introduction

In magnetic fusion devices, turbulent transport is often attributed to long wavelength drift waves whose perpendicular wave-number $k_{\perp}$ normalized to the ion Larmor radius $\rho_i$ is between $0.1 < k_{\perp}\rho_i < 1$. At this scale, two micro-instabilities are frequently dominant in core tokamak plasmas: Ion Temperature Gradient (ITG) and Trapped Electron Modes (TEM) [1]. As different instabilities usually coexist, several modes can couple to each other to give a hybrid or mixed mode turbulence [2]. Discriminating ITG or TEM dominated regimes is then not always possible, and in any case challenging due to their similar scale. However, this is essential to investigate their effects on the plasma parameters and to validate turbulence models.

Although they can induce particle and heat transport of the similar magnitude, their contributions to the ratio $q_i/q_e$ (ion to electron heat flux ratio) or to the direction of the turbulent driven particle pinch, can be noticeably different. Discriminating ITG/TEM from particle or impurity transport requires an accurate evaluation of the diffusion coefficient and the convection velocity. Ideal ITG and TEM rotate in opposite direction in the plasma frame, but the rotation velocity of the plasma itself is usually one order of magnitude higher [3]. Alternately, computation of the mode growth rates, based on measured plasma parameters is widely used to determine which mode is dominant [4]. However, it relies on theoretical predictions and the fastest growing linear mode is not necessarily the one which dominates the turbulent transport.

The identification of direct spectral signatures of fluctuations induced by each instability would be a noticeable progress in physics investigations. A recent study [5] combining Tore Supra and TEXTOR spectra analysis has evidenced that Quasi-Coherent (QC) modes observed by reflectometry [6–8] are linked to TEM. In both devices, QC modes were observed from the plasma core to the gradient region of fusion plasmas. Besides the link established between QC modes and TEM, spectra modifications have also been reported during transitions toward expected TEM-dominated regimes in DIII-D [9–13], and Alcator C-mod [13–16] tokamaks, and in the MST reversed field pinch [17].

Fluctuation spectra showing features similar to QC modes are also observed at the very edge of the plasma in several advanced regimes (H-modes [18–21], Enhanced $D_a$ H-modes [22–25], I-mode [26–28]). There is no unified explanation for these modes which present similar QC spectral signature. To interpret the oscillations detected at the edge, several instabilities have been proposed but TEM. Indeed, TEM are not expected to be unstable in this highly collisional region. To avoid confusion with edge modes, we choose to name QC-TEM the modes linked with TEM that are observed in the core and gradient region of fusion plasmas.

In this article we present a detailed analysis of reflectometry fluctuation spectra in Electron Cyclotron Resonance Heating (ECRH) and Ohmic plasmas, both supporting the link between QC modes and TEM previously evidenced [5]. Section 1 presents the diagnostics set-up and Section 2 describes the main properties of QC-TEM. In
section 3, we show the ECRH effects on QC-TEM in a Tore Supra region where Nickel transport analysis and linear growth rate computation gives indications on the dominant instability. Section 4 presents reflectometry spectra in density ramp-up and current ramp-down performed in JET Ohmic plasmas. A qualitative agreement is found with recent Tore Supra and TEXTOR observations.

1. Diagnostics set-up

This analysis uses conventional reflectometers to study density fluctuation in TEXTOR [29], Tore Supra [30] and JET [31, 32]. Their main properties are summarized in table 1. Conventional reflectometry consists in probing the plasma with an electromagnetic wave, which is reflected at the so-called cut-off layer, and received by the reflectometer. To study density fluctuations at a given position, the probing frequency is kept constant during the time range of interest for spectral analysis. Nonetheless, to probe the plasma at different radial positions, several frequency steps are usually done within a discharge.

I-Q heterodyne systems now commonly used by reflectometers provide $A(t)\cos(\phi(t))$ and $A(t)\sin(\phi(t))$, where $A(t)$ and $\phi(t)$ are the amplitude and the phase, respectively. Hence, the reflectometer signal can be seen as a complex signal $A(t)e^{i\phi(t)}$. The Fourier transform of this complex signal provides spectra with positive and negative frequencies, corresponding to the phase increments and decrements respectively.

Contrary to spectra of Doppler backscattered signals [33], conventional reflectometry spectra are expected to be rather symmetric. However, a small asymmetry is always observed between positive and negative frequencies. It can arise from the combination of different phenomena (Doppler shift induced by plasma rotation, misalignment of the antenna, vertical shift of the plasma position, sawteeth, etc.) [34].

2. QC-TEM properties

2.1. Spectral signature and main characteristics

As previously introduced, in T-10 [7], TEXTOR [6] and Tore Supra [5], reflectometry fluctuation spectra can show QC-TEM oscillations ($30 < f < 150$ kHz) in different regimes. As shown in figure 1, QC modes ($\Delta f \approx f$) are in-between narrow peaks associated to coherent modes such as MHD or GAM ($\Delta f \leq f$) and broad-band fluctuations induced by turbulence ($\Delta f >> f$). They were termed Quasi-Coherent because they oscillate around a given frequency but have an intermediate status, reminiscent of broad-band fluctuations.

In TEXTOR, the several reflectometers installed at different poloidal and toroidal locations [29] allow to perform short-range poloidal correlation and long-range toroidal correlation.

Long-range toroidal correlation shows that QC-TEM modes are the only oscillations which clearly appear in TEXTOR coherence spectra [35]. This has recently allowed to evidence their burst like character and their 3-dimensional nature [8].
Discriminating the Trapped Electron Modes contribution in density fluctuation spectra

Short-range poloidal correlation allows to estimate the perpendicular rotation. These measurements provide the total perpendicular velocity:

$$\Omega_{\perp}^{measured} = \Omega_{\perp}^{E \times B} + \Omega_{\perp}^{phase}$$

(1)

With $\Omega_{\perp}^{E \times B}$ the rotation due to the mean $E \times B$ drift, and $\Omega_{\perp}^{phase}$ the rotation due to the average phase velocity of the mode in the plasma frame. Such measurements were performed from the LFS and the top of TEXTOR. They have shown from the top of the torus only, that QC-TEM rotate faster in the electron diamagnetic direction than lower broad-band frequency fluctuations [5]. As $\Omega_{\perp}^{E \times B}$ is constant at a given position and time, only a distinct $\Omega_{\perp}^{phase}$ can explain such velocity difference (400 m/s). It suggests that $\Omega_{\perp}^{phase}$ is oriented in the electron diamagnetic direction for the QC-TEM (as expected for electron-driven modes) and/or in the ion diamagnetic direction for the low frequencies (as expected for ion-driven modes).

Short-range correlation has also provided an estimation of the poloidal wavelength associated with these QC-TEM oscillations ($0.5 < k_{\perp} < 3 \text{ [cm}^{-1}]$) and their poloidal mode number ($20 < m < 70$) [6]. An estimation of their normalized scale $k_{\perp} \rho_i$ is also possible by using a typical ion temperature profile ($T_i(r/a) = T_i(0) [1 - (r/a)^2]^2$), the central ion temperature $T_i(0) \text{ [eV]}$ being provided by the Artsimovich’s formula valid for Ohmic plasmas [36]:

$$T_i(0) = (1.29 \pm 0.11) \frac{(I_p \cdot B_t \cdot R^2 < n > )^{1/3}}{\sqrt{A_i}}$$

(2)

Where $I_p \text{ [kA]}$ is the plasma current, $B_t \text{ [kG]}$ is the toroidal magnetic field, $R \text{ [cm]}$ is the tokamak major radius, $n \text{ [10^{13} cm^{-3}]}$ is the line-averaged plasma density, and $A_i$ is the atomic mass of the working gas. Figure 2 shows the estimated values of the normalized scale of a set of Ohmic discharges of TEXTOR. It results that $0.4 \leq k_{\perp} \rho_i \leq 0.5$, in good agreement with previous observations always in the range $k_{\perp} \rho_i \leq 1 \text{ [6–8]}$. Such normalized scale is in the range of micro-instabilities such as TEM and ITG.

2.2. Radial and poloidal location

Combining the several reflectometers installed in different tokamak, indications on the location of QC-TEM can be provided. Both poloidal and radial location of QC-TEM is in agreement with expectation for micro-instabilities:

- Radially, QC-TEM can appear at many different radial position, hence they do not depend on a specific location such as the rational surfaces or the separatrix. As an example, observations of QC-TEM have been reported in Tore Supra from $r/a \approx 0.1$ until $r/a \approx 0.8$ [5], depending on the plasma scenario.
- Poloidally, TEXTOR and Tore Supra spectra show that the amplitude of QC-TEM is ballooned on the Low Field Side (LFS) midplane. In TEXTOR, reflectometers can probe the plasma from the LFS midplane and from the top of the torus. Usually, more pronounced QC-TEM are observed at the LFS than at the top [figure 3(a)].
Discriminating the Trapped Electron Modes contribution in density fluctuation spectra

In Tore Supra, where the reflectometers are able to measure on the LFS and on the High Field Side (HFS), most of the time spectra can show QC-TEM on the LFS only [figure 3(b)].

These general properties of QC-TEM (mode number, normalized scale, radial and poloidal location, etc.) pointed toward a link with micro-instabilities. Initial investigations suggested ITG as a driving mechanism [6, 7] but this interpretation has been re-evaluated since regimes in which these modes were observed contradict this interpretation [5].

3. QC-TEM in ECRH plasmas

ECRH has been widely used to destabilize TEM in core tokamak plasmas [9,10,37,38]. Hence, its effect on QC-TEM is investigated with reflectometry fluctuation spectra of Tore Supra ($R = 2.4$ m, $a = 0.72$ m, circular plasma). A power of 250 kW of ECRH was deposited in #40801 discharges with $B_t = 3.8$ T and $I_p = 0.5$ MA. In the ECRH phase, the QC-TEM amplitude is enhanced compared to Ohmic phase [see figure 4(a)] as previously reported in T-10 [39]. In addition, a radial scan performed by changing the reflectometer frequency shows that QC-TEM are large in the core ($r/a < 0.2$), damped between $0.2 < r/a < 0.3$ and not detected further out ($r/a > 0.3$) [see figure 4(b)]. In this discharge, the ECRH power was deposited at $r/a = 0.35$.

This shot belongs to a series of discharges with Nickel injection. The deposition radii of the two gyrotrons were changed keeping the total ECRH power constant: they were either at $r/a = 0.35$ (inner deposition, as on figure 4, #40801) or at $r/a = 0.58$ (outer deposition, #40807), or one at $r/a = 0.35$ and the other one at $r/a = 0.58$ (mixed deposition, #40805). Owing to this combination, we were able to modify the temperature gradient inside $r/a = 0.3$ while keeping the density profile almost constant [40,41]. Switching ECRH on suppresses small sawteeth observed in the Ohmic phase ($T_e < 100$ eV at the crash, inversion radius $(r/a)_{q=1} \approx 0.08$).

Nickel was injected as a trace by a laser blow-off system [42] during the ECRH phase. The impurity behavior was observed with a vacuum ultraviolet spectrometer consisting of a single line of sight in the plasma mid-plane. It measures the time evolution of the Ni XVII line at 24.92 nm, whose time evolution is used as the Ni source term in the transport simulations. Two soft-X-ray cameras with a 2 ms time resolution provide information on impurity radiation in the plasma core. Details on these diagnostics can be found in [42,43].

The radial transport analysis of Nickel is carried out using the ITC code [42]. It solves the system of continuity equations for all the ionization stages of the injected impurity. The impurity flux for each ionization stage results from diffusion and convection:

$$\Gamma_z^p = -D_z(r) \nabla n_z(r) + \nabla_z(r)n_z(r)$$

(3)
Discriminating the Trapped Electron Modes contribution in density fluctuation spectra

Where $D_z(r)$ is the diffusion coefficient and $\vec{V}_z(r)$ the convection velocity. We assume that the diffusion coefficient and the convection velocity are independent of the ionization stage. Starting from an initial guess, ITC solves the system of continuity equations. It then reconstructs the VUV, bolometric and soft X-ray brightnesses. With the help of a genetic algorithm, the code converges towards the transport coefficient profiles best matching the measurements [41].

The analysis performed for the three different ECRH deposition schemes shows that the diffusion coefficient at $r/a = 0.1$ depends strongly on the normalized temperature gradient $R/L_{T_e}$ [figure 5(a)]. On the contrary, at $r/a = 0.3$, the diffusion coefficient is almost independent of $R/L_{T_e}$ [figure 5(b)].

This difference is interpreted in the frame of the theory of turbulent transport. The existence of two regions [41] are observed in linear gyrokinetic simulations [see figure 6] performed with the QuaLiKiz code [4]. In the core, turbulence is dominated by electron modes ($r/a < 0.15$). With TEM dominated turbulence, the transport characteristics are affected by the electron temperature hence explaining figure 5(a). Further out, ($r/a > 0.25$), ITG modes are found dominant. The fact that ITG modes are independent of the electron temperature is consistent with diffusion coefficients independent on $R/L_{T_e}$ [see figure 5(b)].

Thus both in terms of amplitude and radial location, observations of QC-TEM coincide with the excitation of TEM: strong QC-TEM are detected in the core ($r/a < 0.2$) where TEM are dominant. At $r/a \approx 0.3$ where QC-TEM are not observed, both the growth rate computation and the experimental Nickel diffusion coefficient indicate that turbulence is driven by ITG.

4. QC-TEM in Ohmic plasmas

In Ohmic plasmas, the confinement time first increases linearly with density in the Linear Ohmic Confinement (LOC) regime and then saturates in the Saturated Ohmic Confinement (SOC) regime, as shown in figure 7(a). If the onset of an ion mode in the SOC regime was proposed to explain the energy confinement time saturation [44], it is now widely believed that the electrons play a major role, as suggested in [45, 46]. During the last decade, the conventional understanding of turbulence in Ohmic plasma is that the LOC regime is dominated by TEM and the SOC regime by ITG, TEM being stabilized above the LOC-SOC transition. [3, 5, 14, 37, 47–49].

The LOC-SOC transition is predicted to occur at $n_s$ the so-called Shimomura density [50]:

$$n_s = \frac{I_p \mu_0}{2 \pi a^2} \sqrt{\frac{A_i \kappa}{2}}$$  

(4)

Where $a$ is the minor radius of the tokamak, $\kappa$ the plasma elongation, $A_i$ the plasma atomic mass number, $I_p$ the plasma current and $\mu_0$ the vacuum permittivity. As shown by equation 4, $n_s$ is proportional to the plasma current. Hence a transition from the
Discriminating the Trapped Electron Modes contribution in density fluctuation spectra

LOC to the SOC regimes can also be achieved at constant density with a current ramp-down. In the following chapters, both density and current scans performed in Ohmic plasmas are analyzed. One can note that equation 4 provides the plasma parameters whose depends the transition density, but that it does not allow to recover the values of the transition experimentally observed. Hence it cannot be used to determine whether the plasma is in the LOC or the SOC regime.

4.1. Stabilization of QC-TEM by density ramp-up

The advantage of performing density ramp-up to investigate the LOC-SOC transition is that the transition can be rather well identified by looking at the confinement time which saturates in the SOC regime. For reflectometry measurements, the drawback of such analysis is the modification of the cut-off layer locations during the density scan ($r/a \propto n_e$). Thus the probing frequency of the reflectometer has to be changed between each measurement to maintain a constant reflection layer in the plasma.

This was done to observe at $r/a \approx 0.3$ the evolution of QC-TEM in a set of Tore Supra discharges (#41003-41013). Figure 7(b) shows that the “energy” of QC-TEM decreases dramatically between the LOC regime ($\geq 1$) and the SOC regime ($\leq 0.3$). To obtain this energy, the power spectra have been decomposed in several Gaussians corresponding to each of its components (QC-TEM, broad-band, etc.). The energy of QC-TEM being defined by the ratio of the amplitude [dB] divided by the full width at half of its maximum [kHz] of the Gaussian fitting QC-TEM. Figure 7 shows that the QC-TEM stabilization and the LOC-SOC transition are correlated, which support the long-standing hypothesis predicting the stabilization of TEM in the SOC regime.

A density scan ($1.5 < n_e < 2.5$) was also analyzed in JET ($R = 2.96 m$ and $1.25 < a [m] < 2.10$) during an Ohmic discharge in a limited configuration (#87756). Figure 8 which presents reflectometry spectra at different densities shows that a similar picture than Tore Supra is found in JET: QC-TEM appears only at low density. This experiment was not dedicated to the present analysis, consequently the plasma parameters make hazardous the determination of the LOC-SOC transition by confinement time estimation. Hence the comparison with Tore Supra observations remains qualitative.

4.2. Stabilization of QC-TEM by current ramp-down

For reflectometry measurements, performing current scan has the advantage to keep rather constant the measurements location during the scan. The drawback of such analysis is to make more complicated the determination of the LOC-SOC transition which can then be determined by:

- Using previous study related to the LOC-SOC transition. This has been done in TEXTOR [see figure 9(b)], where the transition is expected to occur at $n_e/n_{Gr} \approx 0.55$ [51] with $n_{Gr}$ the Greenwald density ($n_{Gr} = I_p/\pi a^2$).
Using several density scans at different plasma current to plot the transition density as a function of the plasma current. Such plots, which are shown in [15], can be used to determine at which plasma current the transition will occur for a given density. This has been done for a set of Tore Supra discharges [see figure 9(a)].

Figure 9 shows that for both Tore Supra (a) and TEXTOR (b), QC-TEM observed at high current (LOC regime) disappear at low current (SOC regime). Figure 9(c) shows that a similar tendency has been found in JET where high current plasmas ($I_p = 2.45$ and $1.95$ MA) show clear QC-TEM while lower plasma current show no or weak QC-TEM ($I_p = 1.45$ MA). Unfortunately, none of the two methods described above can be used in JET to determine the LOC and SOC regime in current scan. Hence the comparison between devices remains qualitative.

Conclusion and perspectives

QC-TEM with a poloidally ballooned amplitude have been observed from the core to the gradient region at $k_r \rho_i \leq 1$. They have been linked to TEM instabilities by two different methods in three tokamaks of distinct shapes and sizes (Tore Supra, TEXTOR and JET). ECRH increases QC-TEM amplitude only in the core region of Tore Supra where Nickel transport and linear growth rate computation support a TEM-dominated turbulence. In Ohmic plasmas of JET, TEXTOR and Tore Supra, QC-TEM disappear during density ramp-up and current ramp-down. In Tore Supra and TEXTOR, their disappearance has been determined to occur at the LOC-SOC transition where TEM.

Recent results of non-linear gyrokinetic simulations made in Ohmic plasmas support the interpretation of QC-TEM as a direct signature of the fluctuations induced by TEM [52]. Indeed, the simulated frequency spectrum of density fluctuation exhibits a peak reminiscent of QC modes in case of TEM-dominated turbulence only (LOC regime). This finding inferred from a gyrokinetic simulation is in qualitative agreement with observations of frequency spectra from reflectometry data analyzed in this paper.

Detection of QC-TEM can now be used to study the role of TEM in transport. However, the limitation of this technique has to be assessed since QC-modes may not systematically appear in regions where turbulence is dominated by TEM. Difference between ITG and TEM spectra must also be theoretically investigated to understand the reason why these QC oscillations can show-up only when TEM are driven unstable.
